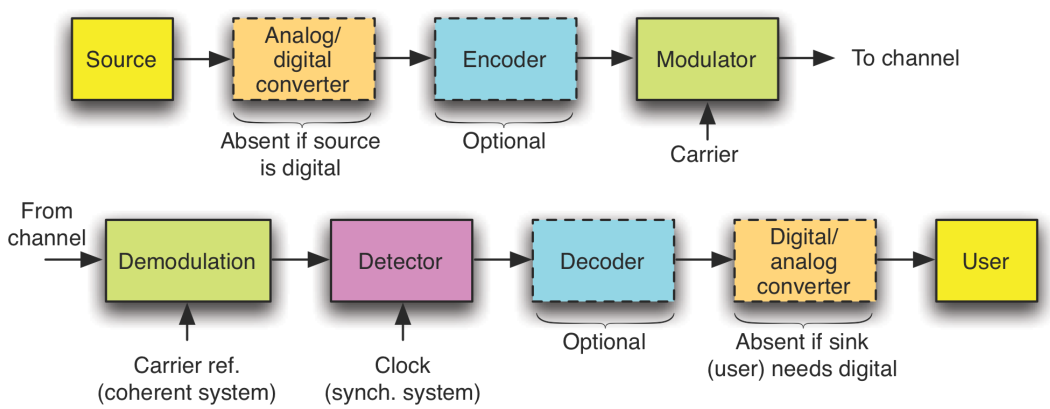
Signal Processing and Communications Hands-On Using scikit-dsp-comm Part 3

Communications Theory & Practice

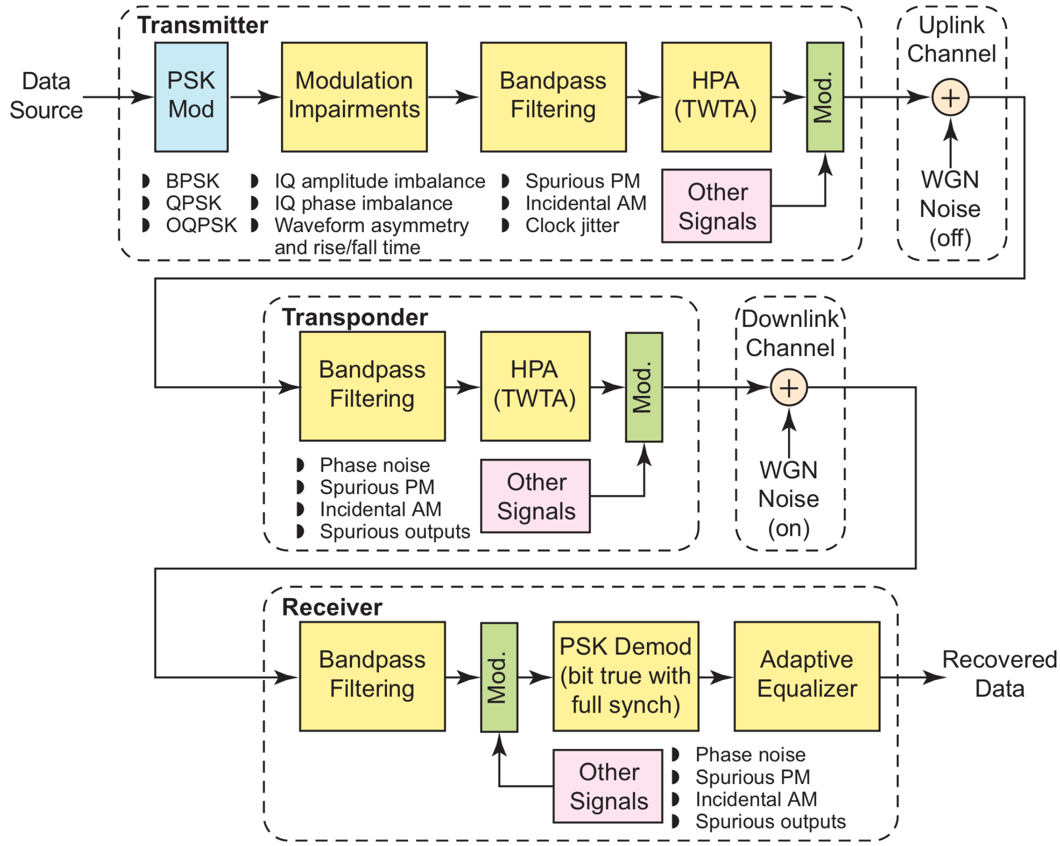
- In this part of the tutorial the focus is on signal processing for communications
- The Labs will involve the use of the RTL-SDR or optionally archived captures found in the tutorial repository

Top Level Block Diagram



- Communication system modeling and simulation are woven throughout all of the `scikit-dsp-comm` package
- The flavors of communication are *analog* and *digital* modulation
  - The above block diagram is digital as bits flow into the encode block and out the decoder block
  - To analog is a misnomer as the channel is waveform based, which is also analog signal processing too
  - In analog communications the message or information signal is directly *modulated* on to the channel

Use Case: Modeling Satellite Commnunications Systems



Wideband Sat-Comm simulation model

Baseband or Carrier Based

- The signals or waveforms that carry communication information are either *baseband* or *carrier* based
- Wired Ethernet is an example of baseband, as are interconnects within our devices
- Wireless communications uses a radio frequency (RF) carrier to allow free space propagation to serve as the channel to carry the signal from the transmitter (tx) to the receiver (rx)
  - There is also free space optical and optical fiber

Carrier Modulation

- A modulated carrier can be represented as

$$x_c(t) = A(t)\cos\left[2\pi f_c t + \phi(t)\right]$$

where $A(t)$ is linear modulation, f_c the carrier frequency, and $\phi(t)$ is phase modulation

- Amplitude modulation is where radio started, and still is in use today in both analog and digital communications
- Phase modulation encompasses frequency modulation (FM) as well, since the two are related by differentiation/integration, e.g.,

- $$\phi(t) = \text{Phase Deviation of the Carrier in radians}$$
$$\frac{1}{2\pi}\cdot\frac{d\phi(t)}{dt} = \text{Frequency Deviation in Hz of the carrier}$$

Carrier Demodulation in Python with the RTL-SDR

- > **Demodulation**: Undoing at the receiver what was done at the transmitter to recover the data bits or analog signal

- As a quick review, an FM modulated carrier applies the message signal $m(t)$ to the carrier signal $x_c(t)$ such that the derivative of the phase deviation, $d\phi(t)/dt$, (also the frequency deviation) is proportional to the message:

$$x_c(t) = A_c \cos\left[2\pi f_c t + \phi(t)\right] = A_c \cos\left[2\pi f_c t + 2\pi k_d \int^t m(\alpha) d\alpha\right],$$

  where k_d is the modulator frequency deviation constant.

- To demodulate FM you first consider the ideal discriminator which takes in $x_c(t)$ and operates on the phase deviation to produce

$$y_D(t) = \frac{1}{2\pi} K_D \frac{d\phi(t)}{dt}$$

  where K_D is the discriminator gain constant

- Notice that for FM, that is $\phi(t) = 2\pi f_D \int^t m(\alpha) d\alpha$ as defined above,

$$y_D(t) = \underbrace{K_D}_{\text{v/Hz}} \cdot \underbrace{f_D}_{\text{v/Hz}} \cdot \underbrace{m(t)}_{\text{v}}$$

- To demodulate FM, the *complex baseband discriminator*, also known as the *quadricorrelator*, has a convenient DSP implementation
- At complex baseband $x_c(t)$ is of the form

$$\tilde{x}_c(t) = \cos[\underbrace{2\pi\Delta f t + \phi(t)}_{\theta(t)}] + j\sin[\underbrace{2\pi\Delta f t + \phi(t)}_{\theta(t)}] = x_I(t) + jx_Q(t),$$

  where I have assumed a small frequency error Δf in the frequency translation of $x_c(t)$ to baseband

- The frequency discriminator obtains $d\theta(t)/dt$ where in terms of the I and Q signals

$$\theta(t) = \tan^{-1}\left(\frac{x_Q(t)}{x_I(t)}\right)$$

- The derivative of $\theta(t)$ is

$$\frac{d\theta(t)}{dt} = \frac{x_I(t)x_Q'(t) - x_I'(t)x_Q(t)}{x_I^2(t) + x_Q^2(t)}$$

- In DSP $x_I(t) \Rightarrow x_I(nT) = x_I[n]$ and $x_Q(t) \rightarrow x_Q(nT) = x_Q[n]$, where T is the sample spacing and $1/T = f_s$ is the sampling rate. The derivatives, $x_I'(t)$ and $x_Q'(t)$, are approximated by the *backwards difference* $x_I[n] - x_I[n-1]$ and $x_Q[n] - x_Q[n-1]$ respectively

- Inside `rtlsdr_helper` this is impolkemented in `y = discrim(x)` as:

```
def discrim(x):
    """
    function disdata = discrim(x)
    where x is an angle modulated signal in complex baseband form.

    Mark Wickert
    """
    X=np.real(x)        # X is the real part of the received signal
    Y=np.imag(x)        # Y is the imaginary part of the received signal
    b=np.array([1, -1]) # filter coefficients for discrete derivative
    a=np.array([1, 0])  # filter coefficients for discrete derivative
    derY=signal.lfilter(b,a,Y)  # derivative of Y,
    derX=signal.lfilter(b,a,X)  #    "          X,
    disdata=(X*derY-Y*derX)/(X**2+Y**2)
    return disdata
```
